Abstract

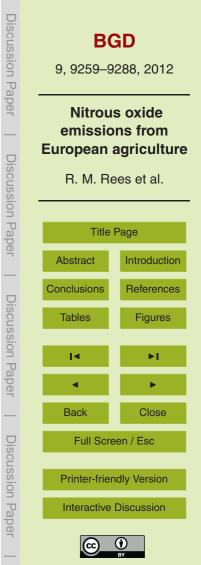

Nitrous oxide emissions from a network of agricultural experiments in Europe and Zimbabwe were used to explore the relative importance of site and management controls of emissions. At each site, a selection of management interventions were compared
 ⁵ within replicated experimental designs in plot based experiments. Arable experiments were conducted at Beano in Italy, El Encin in Spain, Foulum in Denmark, Logården in Sweden, Maulde in Belgium, Paulinenaue in Germany, Harare in Zimbabwe and Tulloch in the UK. Grassland experiments were conducted at Crichton, Nafferton and Peaknaze in the UK, Gödöllö in Hungary, Rzecin in Poland, Zarnekow in Germany and
 ¹⁰ Theix in France. Nitrous oxide emissions were measured at each site over a period of at least two years using static chambers. Emissions varied widely between sites and

- as a result of manipulation treatments. Average site emissions (throughout the study period) varied between 0.04 and 21.21 kg N₂O-N ha⁻¹ yr⁻¹, with the largest fluxes and variability associated with the grassland sites. Total nitrogen addition was found to be
- ¹⁵ the single most important determinant of emissions, accounting for 15% of the variance (using linear regression) in the data from the arable sites (p < 0.0001), and 77% in the grassland sites. The annual emissions from arable sites were significantly greater than those that would be predicted by IPCC default emission factors. Variability in N₂O within sites that occurred as a result of manipulation treatments was greater than that
- 20 resulting from site to site and year to year variation, highlighting the importance of management interventions in contributing to greenhouse gas mitigation.

1 Introduction

25

Terrestrial sources of nitrous oxide (N₂O) make an important contribution to Europe's net emissions of greenhouse gases. A recent continental study identified N₂O as the single most important greenhouse gas emitted from land-based sources with emissions from Europe equivalent to 97 TgCyr^{-1} (Schulze et al., 2009). Agricultural soils

used for grassland and arable production are a major source of N_2O , and strategies to reduce greenhouse gas emissions from the agricultural sector frequently highlight the importance of management interventions (Mosier et al., 1998; Rees, 2011). However, the contribution of management to mitigation can be difficult to assess against

a background of fluxes that are highly variable in time and space, since emissions vary significantly in response to both climate and local environmental (particularly soil) conditions (Abdalla et al., 2010; Flechard et al., 2007; Skiba and Ball, 2002).

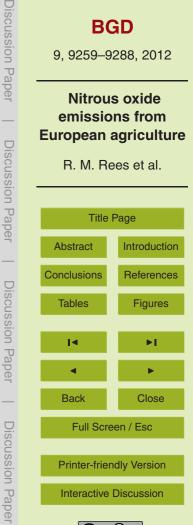

We now have a good understanding of the importance of individual variables in determining emissions, through their effect on the source processes of nitrification and depitrification (Dobbie and Smith 2001; Smith et al. 1998; Wrage et al. 2001) Meta

- denitrification (Dobbie and Smith, 2001; Smith et al., 1998; Wrage et al., 2001). Meta analyses have shown that rates of fertiliser application, and soil properties, such as organic matter content, texture, drainage, pH, fertiliser timing and rate all influence emissions (Bouwman et al., 2002). Within a farming system these factors interact with local climatic conditions to determine overall rates of emission. Climate has been shown to
- ¹⁵ be particularly important in influencing emissions even under constant management. A study of European grasslands showed that the proportion of nitrogen (N) released as N₂O from fertilisers (emission factor) could vary from 0.01–3.6 % compared with the IPCC default value of 1 % (Flechard et al., 2007). Applications of constant amounts of fertiliser N to a grassland site in the UK over several years resulted in variation emis-
- sion factors in different years of between 0.3–7 %, largely as a consequence of varying climatic conditions in different years (Smith and Dobbie, 2002). Variability in Emission Factors used for cereals was smaller, but still showed a five fold variation.

Against such variability, it could be argued that management interventions make a relatively small contribution to the mitigation of emissions. Furthermore such inter-

ventions are constrained by the societal needs to maintain food production, and the most attractive mitigation options are therefore those that increase utilisation of adding nitrogen, and in so doing reducing losses.

In order to explore the relative importance of management, climate and site variability in influencing N_2O emissions we have used a network of 14 experimental sites (eight

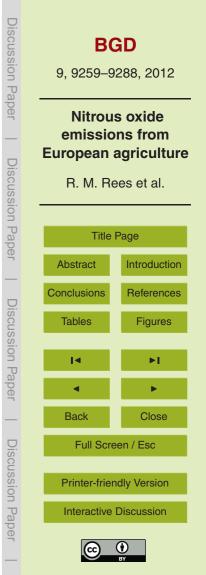

arable and six grassland) established as a part of the NitroEurope project, for the measurement and reporting of N₂O emissions and related environmental drivers. At each site a range of management interventions were compared. Total annual emissions of N₂O from different treatment sites and years showed wide variability. Single variables were often poor predictors of emissions, and so multivariate statistical techniques were used to explore the relationships between annual emissions and underlying driving variables. The aim was to quantify the magnitude of changes in N₂O emission that could result from changes to agricultural management across a network of European sites.

10 2 Materials and methods

15

Manipulation experiments were established at sites across Europe in a co-ordinated research programme (NitroEurope) designed to cover a wide range of climatic conditions. At each site, a selection of management interventions were compared within replicated experimental designs in plot based experiments. Each experiment was used to determine how changes in agricultural management or land use could affect N₂O emissions. Arable experiments were conducted at Beano in Italy, El Encin in Spain,

- Foulum in Denmark, Logården in Sweden, Maulde in Belgium, Paulinenaue in Germany, Tulloch in the UK, and Harare in Zimbabwe. Grassland experiments were conducted at Crichton, Nafferton and Peaknaze in the UK, Gödöllö in Hungary, Rzecin in
- Poland, Zarnekow in Germany and Theix in France. At the arable sites the treatments included alternative tillage treatments, organic and conventional system management, changes in nutrient management (including the amount and form of N added), land use change and drainage treatments. On the grassland sites, treatments included variations in N inputs, wetting, and changes in temperature and atmospheric CO₂ con-
- ²⁵ centration (see Table 1 for further site and experimental manipulations and Table 2 for an overview of soil and climatic conditions). At each site N₂O fluxes were measured using closed static chambers over a period of two years or more, with a minimum of 20

measurements per year (and often including more intensive measurements in periods where fluxes were anticipated, for example following fertiliser applications). As far as possible the methodology used for determining fluxes was standardised across sites (NitroEurope, unpublished). A total of 590 yr of data from individual plot combinations of treatments sites and years were compared in this analysis.

Many of the different chambers used in this study were compared in order to understand the importance of chamber design in determining its ability to quantify a flux (Pihlatie et al., 2009). Gas samples were collected in evacuated glass vials or flushed through vials using a pump (Logarten) and analysed by gas chromatography at all sites except the Belgian and French sites where photoacoustic infrared spectroscopy

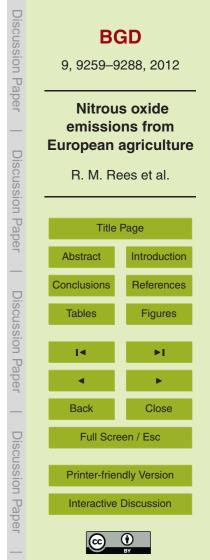

- was used (Boeckx et al., 2011; Cantarel et al., 2011), and fluxes calculated according to standard methodologies (Dobbie and Smith, 2003). One off site measurements of soil carbon, nitrogen, pH, texture, and bulk density were made at each site (Table 2). Records of biological N fixation where legumes were present (using the an empirical approach, Hogh, Jonson et al., 2004). N deposition (EMER 2012). N removal by crops
- ¹⁵ approach, Hogh-Jensen et al., 2004), N deposition (EMEP, 2012), N removal by crops were also reported for each site. Annual N₂O emissions were estimated cumulatively by linear interpolation between individuals of events. The data were collated and N₂O data were log transformed (ln N₂O+1) prior to graphical presentation and analysis using multiple linear regression in Genstat (14th edition) and Minitab (16th edition).

20 3 Results

10

25

Nitrous oxide fluxes varied widely between sites and as a result of manipulation treatments. Average site emissions (throughout the study period) varied between 0.04 and 21.21 kg N₂O-N ha⁻¹ yr⁻¹ (Fig. 2, Tables 3 and 4), with largest fluxes and variability associated with the grassland sites. Within the arable sites the fluxes varied between 0.6 and 5.3 kg N₂O-N ha⁻¹ yr⁻¹, with the highest average fluxes observed from the Belgium tillage experiment at Maulde. The highest average grassland flux (21.2 kg N₂O-N ha⁻¹ yr⁻¹) was observed from Crichton, an experiment located on an intensive

dairy farm (receiving high inputs of inorganic and organic N) in the south-west of Scotland.

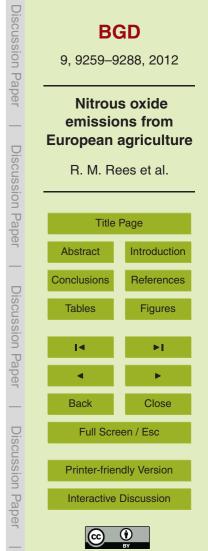

Within each site there was considerable variability in N_2O emissions resulting from year to year changes in climatic conditions and the manipulation treatments applied. An

⁵ example of this variability is illustrated by considering fluxes from the Crichton grassland site. The annual average emission was 21.2 kg N₂O-N ha⁻¹ yr⁻¹, however, this varied between 2.9 and 33.9 kg N₂O-N ha⁻¹ yr⁻¹ in different treatments in 2007 (Fig. 2c, Table 3). There was also an annual variability (expressed as the difference between the mean emissions in each year) of 15.3 kg N₂O-N ha⁻¹ yr⁻¹.

¹⁰ A comparison of treatment effects and annual climatic effects across different sites demonstrated that treatments applied to arable sites resulted in a range of emissions between treatments that was greater than that observed between sites (Tables 3 and 4). At the Tulloch organic farming experiment for example, the range in treatment emissions (averaged over years) was 0.5–13.2 kg N₂O-N ha⁻¹ yr⁻¹, while the range

¹⁵ in the mean emission across all European arable sites was between 0.6–5.31 kg N₂O-N ha⁻¹ yr⁻¹ (Table 3). The variability in annual flux data showed reasonable consistency across sites with the annual average flux being of similar magnitude to the standard deviation (Table 3). Annual variability within sites was also important. The range of emissions between years (averaged over all treatments) at the El Encin site was 0.31–0.97 kg N₂O-N ha⁻¹ yr⁻¹, which was less than the range between sites 0.6–5.3 kg N₂O-N ha⁻¹ yr⁻¹ (Table 4a). In grassland sites treatments there was a range between treatments of 2.9–28.2 kg N₂O-N ha⁻¹ yr⁻¹ at the Crichton site which was comparable with the range of 0.04–21.21 kg N₂O-N ha⁻¹ yr⁻¹ between sites (Table 4b).

An analysis of all annual data from across the different sites and years was used to identify the importance of a range of driving variables. Within the arable sites total nitrogen input (in the form of organic N and/or synthetic N fertiliser) was the single most important determinant of emissions, accounting for 14.6 % of the variance in the data by linear regression (p < 0.0001; Fig. 3). Another notable feature of this regression analysis was the wide range of emissions (0–21 kg N₂O-N ha⁻¹) associated with

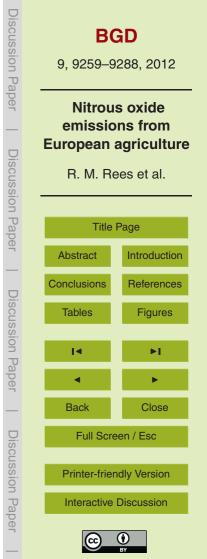

sites receiving no added N (synthetic fertiliser or manure). Adding the additional terms (deposition, average daily temperature, total water applied including precipitation and irrigation, bulk density and SOC) to this regression against the natural log of the annual N₂O emission through a step-wise procedure increased the amount of variability

- ⁵ accounted for to 37.1 %. However, when site and year are included in the stepwise regression, the added terms included average daily temperature and total water applied, 49.1 % of the variability was explained. Therefore, there are features of the sites and years (relating to soils and management) that impact on emissions. However, it was noted that, soil organic carbon and bulk density were not significant factors. In the case
- ¹⁰ of the grassland sites, total nitrogen input explained 76.9 % of the variation (Fig. 4). The high N additions and N_2O emissions from the Crichton grasslands were important in contributing to the strength of this regression. Adding the total water applied and bulk density to the regression improved the variability explained to 81.4 %.

The emissions data presented here can also be used to identify those systems with the highest emissions (and therefore greatest mitigation potential). When the plots from all 438 site and treatment years from the arable experiments were compared, the ten highest emissions were observed at just three sites when expressed on an emission per unit area basis; these were Tulloch, Beano, and Maulde (Fig. 5a). When expressed on an intensity basis the ten highest emissions were also observed at three sites; Tulloch, Harare and Logården, with values ranging from 1.4–3.9 kg N₂O-N kg total N added⁻¹ (Fig. 5b). Emissions from the grassland sites were generally lower than those from the arable sites with the exception of Crichton where emissions were approxi-

mately 2 orders of magnitude higher than other grassland sites (Fig. 6).

A three dimensional plot of N_2O emissions against annual total rainfall and irrigation and total annual N addition emphasises the combined affect of N addition and total water addition in determining, emissions. Under dry conditions with 500 mm of rainfall or less, emissions remained below $3 \text{ kg } N_2O$ -N ha⁻¹ at rates of N application of up to 450 kg ha^{-1} , however, as the rainfall and irrigation increased to 1500 mm, emissions rose to around 10 kg N_2O -N ha⁻¹ (Fig. 7).

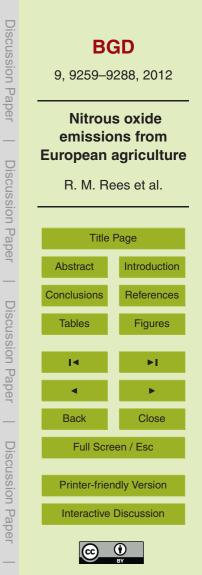

4 Discussion

We know from previous studies that emissions of N_2O from landscapes are controlled by site specific factors such as soil conditions and climate as well as the way in which these systems are managed (e.g. fertiliser use and agronomy) (Dobbie et al., 1999;

- ⁵ Smith and Conen, 2004). This study has allowed us to compare the relative magnitude of these effects across a large number of sites, and has demonstrated that the changes associated with management interventions are equal to or greater that those associated with differences between site and year. There was a large variability in fluxes observed as a consequence of manipulation treatments introduced within each site
- and between measurement years. Characterising the magnitude of potential mitigation is an essential prerequisite for the implementation of policies designed at reducing greenhouse gas emissions from the agricultural sector. It has been suggested that interventions which include better nutrient use efficiency, improved soil management and improved agronomy could achieve a reduction in emissions of 10–30 % (Mosier et al.,
- ¹⁵ 1998; Smith et al., 1997). The results presented here are consistent with these estimates, and have highlighted the importance of reducing the N supply in contributing to mitigation.

The change in emissions associated with increasing N inputs was not always consistent with the emissions that would be estimated by default IPCC emissions factors where 1 % of added N would be predicted to be lost as N₂O (IPCC, 2006). In the arable sites emissions were 37 % greater than this value, and despite the large variability, this was significantly greater (*P* < 0.0001) than 1 % of N inputs. The grassland sites did not show a significant difference from the default emission factor, but relatively few of these sites included N addition. The largest proportional changes in emissions were associated with changes in the inputs of N and irrigation at the Spanish site, which contributed to a 26 fold change in emissions, and changes across the different phases of an organic rotation (Tulloch) in the UK. The affects of reducing tillage treatments resulted in a much smaller proportional change (increased N₂O emissions) in Italy and

Belgium (Alberti et al., 2010; Boeckx et al., 2011). However, it should be considered that reducing tillage intensity also results in increased C storage, and so the affects on net greenhouse gas emissions may be less than that indicated by N_2O emissions. There is also emerging evidence to suggest that in the longer term, N_2O emissions from reduced till systems may be lower than that from conventional tillage (Six et al., 2004).

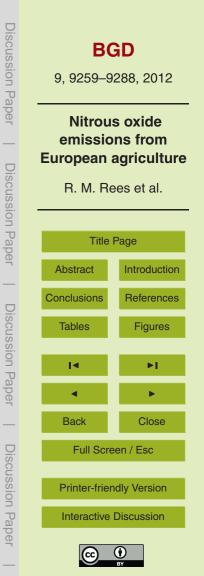

5

There was a significant effect of N addition across all sites on N₂O emissions, as illustrated by the regression analysis, which is consistent with previous meta-analyses of N₂O emissions (Bouwman et al., 2002). However, it was not possible to explain more than 23 % of the variability in emissions by N input from synthetic fertilisers and manures alone. The large range of emissions associated with sites receiving no N as fertiliser or manure is of particular importance. Many of these sites would receive N by biological fixation from leguminous crops sometimes over a period of several years prior to flux measurements. Biological N fixation is assumed by IPCC not to be directly associated with increased emissions as a consequence of residue decomposition by legumes. The magnitude of such emissions remains highly uncertain and is likely to

be highly site specific (Baggs et al., 2000; Rochette and Janzen, 2005).
 Another factor potentially contributing to emissions from unfertilised sites and not
 accounted for in this study would be the mineralisation of soil organic matter. Following land use change or within rotational systems there may be a release of mineral N from the organic N pool due to tillage, providing a substrate for nitrification and denitrifica-

tion driven N_2O release. In organic farming systems this build-up of organic N within the grassland phase of a rotation is used to provide nutrients (particularly N) for subse-

quent arable crops (Stockdale et al., 2001; Watson et al., 2011). This can lead to some high emissions in individual years from organic farming systems, particularly where the system exists in mild and wet climates such as that at Scottish organic site at Tulloch (despite no apparent input of N in that year). However, high emissions from individual years within an organic phase of an organic rotation are often offset by lower emissions

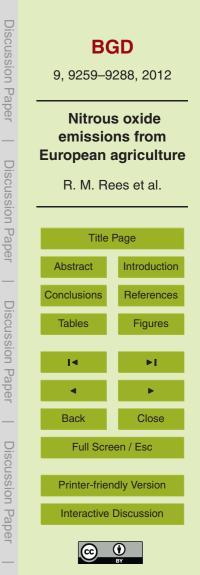

during the grassland phase giving relatively low emissions from the system overall (Ball et al., 2002). In this study the average emissions over the three cropped organic sites was $1.58 \text{ kg } \text{N}_2\text{O-N} \text{ ha}^{-1}$ compared with an overall mean of $2.37 \text{ kg } \text{N}_2\text{O-N} \text{ ha}^{-1}$ from the arable sites.

- ⁵ There is a trade-off between reducing N₂O emissions by reduced N input and food production, since restricting N input can often lead to proportional decreases in crop yields and an effective displacement of emissions, since reductions in emissions that are achieved by lowering production can lead to an import of food which itself would be associated with emissions (Godfray et al., 2011).
- For this reason the emissions intensity provides a useful index of the effectiveness of mitigation. Some of the highest emission intensities were associated with individual phases of organic rotations at Tulloch (4.0 g N₂O-N Kg N uptake⁻¹) and Logården (2.1 g N₂O-N Kg N uptake⁻¹). This highlights the need to increase the utilisation efficiency of N between different crop types within some production systems in order to lower emission intensities.

The implementation of mitigation measures to reduce N₂O emissions from agriculture is likely to depend on regionally specific changes in management practice that take account of local soil and climatic conditions. We have shown that those locations associated with high N inputs and high annual rainfall and irrigation (above 1000 mm) are most prone to large emissions. El Encin is an example of such a site, and studies there have identified inorganic fertiliser N as being a particularly important contributor to emissions. Studies at the Spanish site were able to demonstrate that replacement of fertiliser by organic N substrates, or the combination of organic and synthetic fertiliser was able to reduce emissions of N₂O significantly (Meijide et al., 2009; Sanchez-Martin et al., 2010).

A number of sites reported a net annual uptake of N_2O within individual plots of a treatment. This included 12 plots at El Encin, 7 from Zimbabwe, 2 at Logården and one at Maulde. Dry or well drained soil conditions together with low N availability appear to favour net uptake. The mechanism responsible is uncertain, but is likely to involve

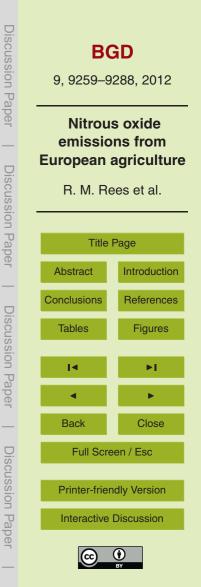

the use of N₂O as a terminal electron acceptor in circumstances where soil aggregation allows uptake of N₂O from the air into oxygen depleted sites where N₂O can be used instead of O₂ (Neftel et al., 2007).

The grassland sites included in this study were very diverse, but included only one
⁵ highly intensive production system on a dairy farm in Scotland (Crichton). Here emissions were higher than any measured from elsewhere in the arable and grassland sites. This was a reflection of the high N input (specifically in 2007 where total inputs in one treatment exceeded 600 kg N ha⁻¹ yr⁻¹ in some treatments) and mild and wet conditions that occur throughout the year and which are conducive to high N₂O emissions
¹⁰ (Flechard et al., 2007). The remaining grassland sites received much lower N inputs and were generally associated with low N₂O emissions, highlighting the importance of N input in driving N₂O emissions.

5 Conclusions

This study has allowed a wide ranging comparison of the relative importance of agri¹⁵ cultural management and site specific determinant of N₂O emissions. The magnitude of emissions varies widely, and N input to systems was shown to be the principal driver across sites and treatments. Grasslands with high N input showed the largest annual emissions, but arable sites receiving high N and water inputs were also prone to large emissions, thus illustrating the importance of restricting N supply in controlling N₂O
²⁰ emissions. There was a significantly greater emission of N₂O from N added to arable sites than would be predicted from IPCC default emission factors. This study has also demonstrated that while site (and climate) are important determinants of the magnitude of N₂O emissions, agricultural management practices are of equal or greater importance.

* The Crichton experiment involved the comparison of regionally typical management scenarios on adjacent fields in different years.

** The Rzecin/Zarnekow experiment involved the comparison of a dying/wetting and flooding experiments in Zarnekow (Germany), with a control site in Rzecin (Poland).

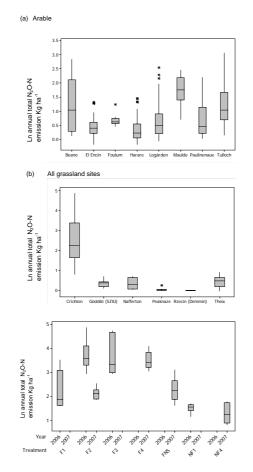

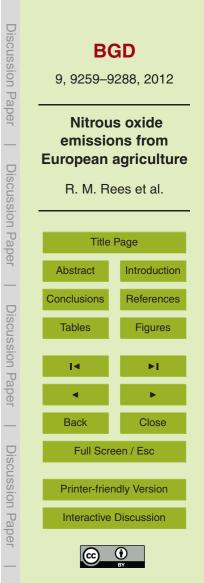

Fig. 2. Annual N₂O emissions compared between sites. Each bar represents the average emission from different treatments in different years. Each bar indicates the mean (central bar), upper and lower quartiles (outside bar) and 95% range (lines). Outliers are represented by asterisks. See Table 1 for a description of the detailed treatment codes.

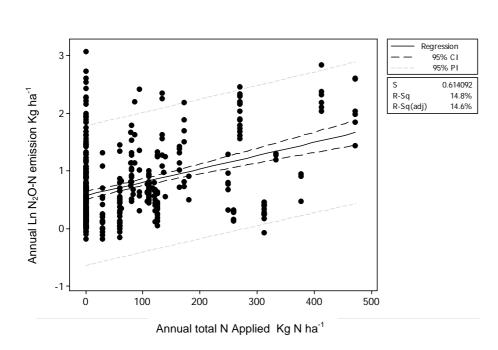

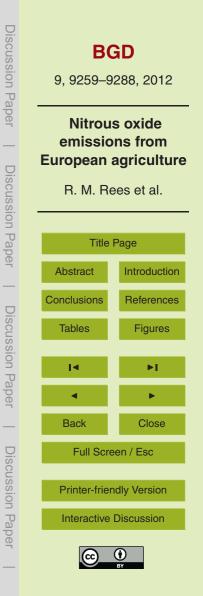

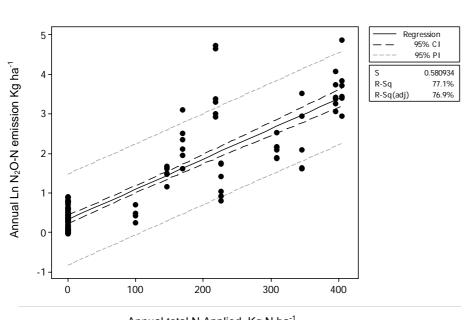

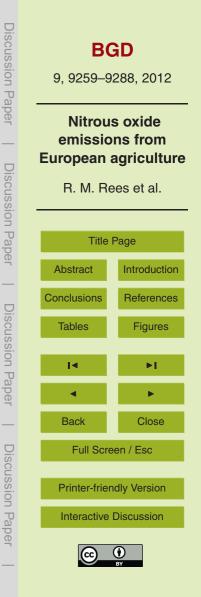

Fig. 3. The relationship between N₂O emissions and added N input (in the form of organic manures and synthetic N fertiliser) for arable sites. $ln(N_2O)$ (kg N₂O-N ha⁻¹) = 0.5750 + 0.002602 total N applied.

Annual total N Applied Kg N ha-1

Fig. 4. The relationship between N₂O emissions and added N input (in the form of organic manures and synthetic N fertiliser) for grassland sites. $ln(N_2O)$ (kg N₂O-N ha⁻¹) = 0.3342 + 0.007631 total N applied.

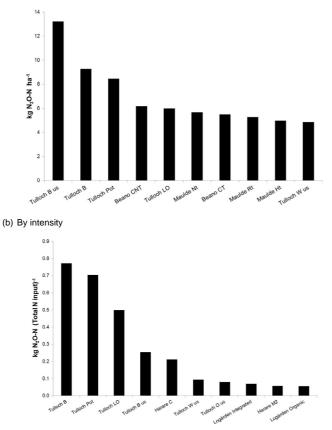

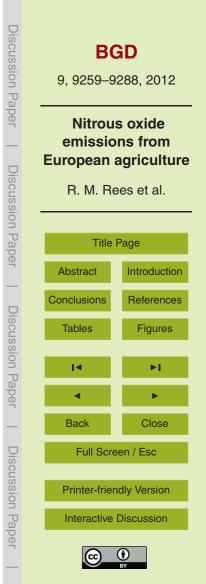

Fig. 5. Ranking of annual emissions data from individual arable plots. The top 10 sites are ranked on emissions per unit area **(a)** and per unit of N_2O per unit of N total input (synthetic fertiliser, manure and biological N fixation) **(b)**. See Table 1 for a description of the treatment codes.

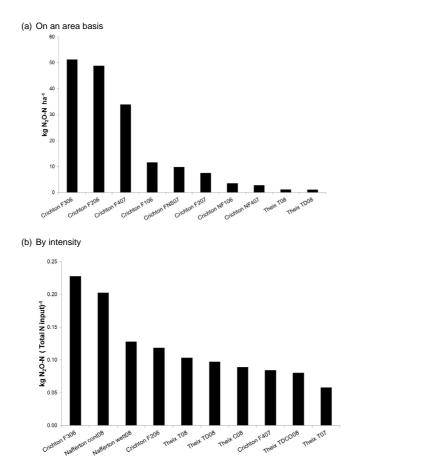

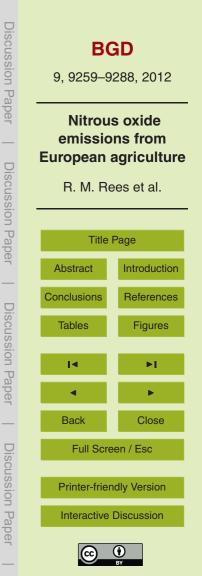

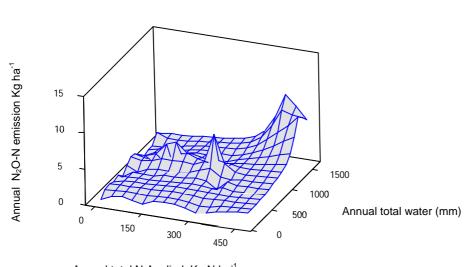

Fig. 6. Ranking of annual emissions data from individual grassland plots. The top 10 sites are ranked on emissions per unit of N_2O per unit of N total input (synthetic fertiliser, manure, deposition and biological N fixation). See Table 1 for a description of the treatment codes.

Annual total N Applied Kg N ha⁻¹

Fig. 7. The relationship between N_2O emissions and annual total rainfall plus irrigation and total N input across the arable site network.
